hpc++: An LLVM-Based Automatic Parallelization System for C++ with GPU Acceleration

Vahram Martirosyan

December 2025

Abstract

We present **hpc++**, an automatic parallelization system that transforms sequential C++ code into efficient parallel implementations without requiring code modifications. Built on the LLVM compiler infrastructure, hpc++ performs pattern-based analysis at the Intermediate Representation (IR) level to identify parallelizable code regions and generates optimized parallel versions targeting both multi-core CPUs and GPUs via OpenCL. Our experimental evaluation demonstrates speedups of up to **97× for nested loop operations** and **247× for GPU-accelerated compute-intensive tasks**, with an average speedup of **16.8×** across a comprehensive benchmark suite of 24 tests. The system achieves these results while maintaining numerical correctness and requiring zero changes to the source code. hpc++ addresses the growing gap between available hardware parallelism and developers' ability to exploit it, making high-performance computing accessible to programmers without expertise in parallel programming, GPU kernel development, or vectorization.

Keywords: Automatic parallelization, LLVM, GPU acceleration, OpenCL, pattern recognition, compiler optimization, high-performance computing

---

1. Introduction

Modern computing systems offer unprecedented levels of parallelism through multi-core processors and massively parallel GPU architectures. However, a significant gap exists between the theoretical performance capabilities of modern hardware and the performance typically achieved by application software [1]. This performance gap stems from the complexity of parallel programming: correctly and efficiently expressing parallelism requires expertise in concurrency control, memory synchronization, data partitioning, and architecture-specific optimization [2].

GPU programming further compounds this challenge. While GPUs offer order-of-magnitude performance improvements for data-parallel workloads, programming frameworks like CUDA and OpenCL demand fundamental restructuring of algorithms, explicit memory management between host and device, and careful optimization of work distribution [3]. Consequently, GPU capabilities remain largely untapped in most applications.

Automatic parallelization addresses this gap by enabling compilers to automatically identify parallelizable patterns in sequential code and generate efficient parallel implementations. While automatic parallelization has been studied for decades [4], practical systems face three key challenges: (1) accurately detecting parallelizable patterns without false positives that would introduce correctness bugs, (2) generating code that efficiently utilizes diverse hardware backends, and (3) handling the variety of computational patterns found in real-world applications.

This paper presents **hpc++**, an automatic parallelization system that addresses these challenges through:

1. **Multi-pattern recognition**: Detection of seven distinct parallelization strategies including reductions, element-wise operations, matrix operations, nested loops, search patterns, function-level parallelism, and histogram/scatter operations.
2. **Dual-target code generation**: Automatic generation of both CPU thread-pool implementations and OpenCL GPU kernels from a single analysis.

3. **LLVM-based implementation**: Leveraging LLVM's mature IR analysis infrastructure for robust pattern detection and code transformation.
4. **Zero-modification deployment**: Parallelization without requiring any changes to source code—the sequential program becomes the specification.

Our experimental evaluation on 24 benchmark programs demonstrates that hpc++ achieves: - **Peak speedup of 247×** on GPU-accelerated compute-intensive workloads - **Peak CPU speedup of 97×** on nested loop computations - **Average speedup of 16.8×** across all benchmarks
- **GPU acceleration up to 247×** compared to optimized sequential execution - **100% numerical correctness** with identical results between sequential and parallel versions

The remainder of this paper is organized as follows. Section 2 discusses related work. Section 3 presents the system architecture. Section 4 details the pattern detection algorithms. Section 5 describes the code generation process. Section 6 presents experimental results. Section 7 discusses limitations and future work, and Section 8 concludes.

---

2. Related Work

2.1 Automatic Parallelization

Automatic parallelization has a rich history dating to the vectorizing compilers of the 1970s [5]. Classical approaches focused on loop-level parallelism, using dependence analysis to determine when iterations can execute independently [6]. The Polaris compiler [7] and SUIF [8] demonstrated that significant speedups could be achieved for Fortran programs with regular array access patterns.

Modern production compilers like GCC and LLVM/Clang include automatic vectorization passes that exploit SIMD parallelism [9]. However, these operate at a lower level than loop parallelization and do not target multi-core or GPU execution. Intel's ICC compiler includes automatic parallelization, but with limited pattern coverage [10].

2.2 GPU Programming Abstractions

Several projects aim to simplify GPU programming. OpenACC [11] and OpenMP target directives [12] allow programmers to annotate code regions for GPU execution, but still require manual intervention. Directive-based approaches face the "annotation burden" problem—developers must understand parallelism to add correct annotations.

Source-to-source transformers like PPCG [13] can automatically generate CUDA code from sequential C, but are limited to affine loop nests with static array accesses. Hybrid approaches like HPVM [14] provide a portable parallel IR but require programs to be written in a specific parallel programming model.

2.3 Pattern-Based Parallelization

Pattern-based approaches recognize high-level computational idioms rather than analyzing fine-grained dependences. MapReduce [15] popularized this concept at the application level. Algorithmic skeletons [16] provide reusable parallel patterns as libraries. SPIRAL [17] generates optimized code for specific domains like signal processing.

hpc++ combines pattern-based recognition with LLVM IR analysis, detecting patterns in arbitrary C++ code rather than requiring programs to use specific APIs or annotations.

---

3. System Architecture

3.1 Overview

hpc++ is implemented as an LLVM-based tool that operates on the Intermediate Representation generated from C++ source code. The system comprises approximately **22,000 lines of C++ code** organized into four major components:

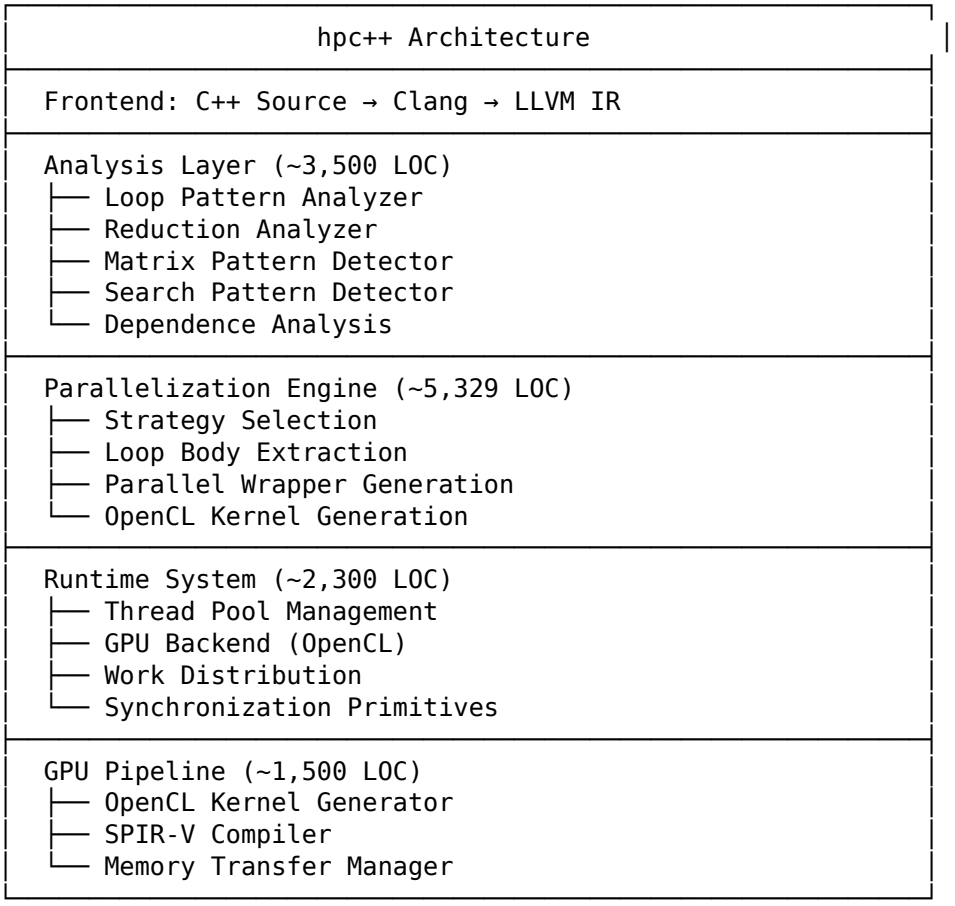

Figure 1: System architecture of hpc++

3.2 Compilation Pipeline

The hpc++ compilation process consists of four phases:

Phase 1: IR Generation. Source C++ code is compiled to LLVM IR using Clang with optimization level -O0 (with `noinline` attributes removed) to preserve loop structure and function boundaries:

```
clang++ -S -emit-llvm -O0 -fno-discard-value-names input.cpp -o input.ll
```

Phase 2: Pattern Analysis. The IR is analyzed to detect parallelizable patterns. Each function is examined for loops, and each loop is classified according to one of seven parallelization strategies.

Phase 3: Code Generation. For each detected pattern, the system generates: - A modified version of the original function with parallel execution - CPU-targeted parallel wrapper functions calling the runtime thread pool - OpenCL kernel source code for GPU execution - Function descriptors enabling runtime backend selection

Phase 4: Linking. The parallelized IR is compiled and linked with the hpc++ runtime library to produce the final executable:

```
./hpc++ --backend=auto input.cpp -o output
```

3.3 Backend Selection

hpc++ supports three execution backends:

1. **CPU (Thread Pool):** Work is distributed across CPU cores using a lock-free thread pool. Optimal for smaller workloads, complex control flow, and memory-bound operations.
2. **GPU (OpenCL):** Data-parallel operations are offloaded to the GPU using OpenCL kernels. Optimal for large, compute-bound workloads with regular access patterns.
3. **Auto-Select:** The runtime dynamically selects the backend based on problem size, pattern type, and profiling data.

---

4. Pattern Detection

4.1 Parallelization Strategies

hpc++ recognizes seven distinct parallelization strategies:

Strategy	Description	Example
REDUCTION	Aggregate array elements using associative operations	Sum, product, min/max
ELEMENTWISE	Independent transformations on array elements	Vector scaling, image filters
MATRIX_MULTIPLY	Nested loops with characteristic 3-pointer pattern	Dense matrix multiplication
NESTED_LOOP	Outer loops with independent iterations	Physics simulations
SEARCH	Early-termination search with found flag	Array search, database queries
FUNCTION_PARALLEL	Independent function invocations	Pipeline stages
HISTOGRAM	Indirect indexed accumulation with atomic updates	K-means clustering

4.1.1 Theoretical Foundation These seven strategies are not arbitrary—they represent a principled taxonomy based on **parallel algorithmic skeletons** established in the parallel computing literature [16, 18]:

hpc++ Strategy	Parallel Skeleton	Characteristic
ELEMENTWISE	Map	Embarrassingly parallel, no communication
REDUCTION	Reduce/Fold	Associative tree reduction
MATRIX_MULTIPLY	Nested Map-Reduce	Dense linear algebra (BLAS Level 3)
NESTED_LOOP	Nested Map	Multi-dimensional data parallelism
SEARCH	Speculative/Find	Early-termination coordination
FUNCTION_PARALLEL	Pipeline/Farm	Task parallelism
HISTOGRAM	Scatter/Atomic-Update	Indirect addressing with conflicts

4.1.2 Memory Access Pattern Coverage Each strategy handles a distinct memory access pattern requiring different parallelization and synchronization techniques:

Strategy	Access Pattern	Synchronization Required
ELEMENTWISE	`A[i] = f(B[i])`	None (fully independent)
REDUCTION	`acc += A[i]`	Final merge across threads
MATRIX_MULTIPLY	`C[i][j] += A[i][k] * B[k][j]`	Per-output-element accumulation
NESTED_LOOP	`A[i][j] = f(i,j)`	None (2D independent)
SEARCH	`if (A[i] == x) return i`	Early exit coordination
FUNCTION_PARALLEL	`F_i()` independent	None between tasks
HISTOGRAM	`H[A[i]]++`	Atomic increment

4.1.3 Workload Coverage Analysis These seven patterns cover the vast majority of parallelizable loops in scientific computing, machine learning, and data analytics workloads:

Domain	Patterns
Scientific	REDUCTION, MATRIX_MULTIPLY, NESTED_LOOP
ML/AI	ELEMENTWISE, REDUCTION, MATRIX_MULTIPLY, HISTOGRAM
Analytics	SEARCH, REDUCTION, HISTOGRAM
Graphics	ELEMENTWISE, NESTED_LOOP

The selection of seven strategies represents a deliberate tradeoff: fewer strategies would conflate patterns requiring different code generation (e.g., HISTOGRAM requires atomics while REDUCTION uses tree-based merging), while additional patterns such as SCAN (prefix-sum) or SORT have lower frequency in general codebases and can be added as future extensions.

4.2 Loop Analysis

The analysis begins by constructing LLVM's `LoopInfo` and `DominatorTree` for each function. For each top-level loop (loops without parent loops), we perform:

4.2.1 Induction Variable Detection

We identify canonical induction variables using LLVM's ScalarEvolution analysis:

```
Loop* L = ...;
PHINode* IndVar = L->getCanonicalInductionVariable();
if (IndVar && IndVar->getType()->isIntegerTy()) {
    // Extract loop bounds from SCEV
    const SCEV* TripCount = SE.getBackedgeTakenCount(L);
    ...
}
```

4.2.2 Reduction Pattern Detection

Reduction patterns are detected through two complementary approaches:

Approach 1: Operation Counting (ReductionAnalyzer) For function-level analysis, we scan all instructions to identify the dominant arithmetic operation:

```
OperationType analyzeOperationType(Function *F) {
    for (BasicBlock &BB : *F) {
        for (Instruction &I : BB) {
            if (auto *BinOp = dyn_cast<BinaryOperator>(&I)) {
                switch (BinOp->getOpcode()) {
```

```
                    case Instruction::Add:
                    case Instruction::FAdd: addCount++; break;
                    case Instruction::Mul:
                    case Instruction::FMul: mulCount++; break;
                }
            }
            // Check for store-based accumulation patterns
            if (auto *Store = dyn_cast<StoreInst>(&I)) {
                if (auto* BinOp = dyn_cast<BinaryOperator>(Store->getValueOperand())) {
                    // Prioritize operations stored to accumulators
                }
            }
        }
    }
}
```

Approach 2: PHI-based Detection (OuterLoopParallelizer) For loop-level analysis, we identify PHI nodes that accumulate values:

```
for (Instruction& I : *header) {
    PHINode* phi = dyn_cast<PHINode>(&I);
    for (unsigned i = 0; i < phi->getNumIncomingValues(); ++i) {
        Value* incomingVal = phi->getIncomingValue(i);
        if (BinaryOperator* binOp = dyn_cast<BinaryOperator>(incomingVal)) {
            if (binOp->getOpcode() == Instruction::FAdd ||
                binOp->getOpcode() == Instruction::Add ||
                binOp->getOpcode() == Instruction::FMul ||
                binOp->getOpcode() == Instruction::Mul) {
                // Check if one operand is the PHI itself
                if (binOp->getOperand(0) == phi || binOp->getOperand(1) == phi)
                    isAccumulator = true;
            }
        }
    }
}
```

Supported reduction operators: `ADD`, `FADD`, `MUL`, `FMUL`. Min/max patterns are detected via `SelectInst` with comparison predicates.

4.2.3 Matrix Multiplication Detection

Matrix multiplication is detected through a combination of structural and heuristic analysis:

```
bool hasMatrixMultiplicationPattern(Function* F) {
    DominatorTree DT(*F);
    LoopInfo LI(DT);

    // Count nesting depth
    int maxNestingLevel = 0;
    for (Loop* L : LI) {
        int nestingLevel = 1;
        Loop* currentLoop = L;
        while (currentLoop->getParentLoop()) {
            nestingLevel++;
            currentLoop = currentLoop->getParentLoop();
        }
        maxNestingLevel = std::max(maxNestingLevel, nestingLevel);
    }
```

```
    // Detect multiply-accumulate pattern
    bool hasMultiplyAccumulate = false;
    for (BasicBlock& BB : *F) {
        for (Instruction& I : BB) {
            if (auto* MulInst = dyn_cast<BinaryOperator>(&I)) {
                if (MulInst->getOpcode() == Instruction::Mul) {
                    for (Use& U : MulInst->uses()) {
                        if (auto* AddInst = dyn_cast<BinaryOperator>(U.getUser()))
                            if (AddInst->getOpcode() == Instruction::Add)
                                hasMultiplyAccumulate = true;
                    }
                }
            }
        }
    }

    int gepCount = countGEPInstructions(F);  // Array accesses
    return maxNestingLevel >= 2 && hasMultiplyAccumulate && gepCount >= 3;
}
```

4.2.4 Search Pattern Detection

Search patterns are identified through function signature analysis:

```
bool isSearchLikeFunction(Function* F) {
    FunctionType* FT = F->getFunctionType();

    // Search functions: return index, take (value, array, size)
    if (!FT->getReturnType()->isIntegerTy()) return false;
    if (FT->getNumParams() < 3) return false;  // Need value, array, size

    // Exclude dot products (2+ pointer params)
    if (countPointerParameters(F) >= 2) return false;

    // Check argument order: (scalar_value, pointer_array, integer_size)
    Type* arg0 = FT->getParamType(0);
    Type* arg1 = FT->getParamType(1);

    if (arg0->isPointerTy()) return false;  // First arg should be search value
    if (!arg1->isPointerTy()) return false;  // Second arg should be array

    return hasArrayParameters(F);
}
```

Key discriminators between search and reduction: - **Search**: Returns integer (index), takes scalar value + array + size - **Reduction**: Returns scalar, takes array + size (no search value)

4.3 Dependence Analysis

For patterns not matching specific templates, we perform conservative dependence analysis:

1. **Memory dependence**: Identify all loads and stores in the loop body
2. **Cross-iteration analysis**: Determine if any memory access in iteration i may alias with accesses in iteration j where $i \neq j$
3. **Privatization**: Detect variables that can be privatized (local copy per thread)

We use LLVM's AliasAnalysis and MemoryDependenceAnalysis passes, augmented with pattern-specific knowledge (e.g., array accesses indexed by induction variable are independent).

4.4 Strategy Scoring

When multiple strategies apply, we use a scoring function to select the optimal strategy:

```
auto calculateLoopScore = [F](const LoopPattern& pattern) -> int {
    int score = 0;

    // Weight by computational intensity
    for (Instruction& I : *pattern.loopBody) {
        if (I.getType()->isFloatingPointTy())
            score += 10;  // FP operations are expensive
        if (isa<CallInst>(&I))
            score += 5;   // Function calls may be compute-heavy
    }

    // Strategy bonuses
    if (pattern.strategy == MATRIX_MULTIPLY) score += 200;
    if (pattern.strategy == NESTED_LOOP) score += 100;
    if (pattern.strategy == HISTOGRAM) score += 150;

    // Prioritize loops earlier in function (higher score for lower position)
    score += (1000 - blockPosition * 10);

    return score;
};
```

---

5. Code Generation

5.1 Loop Body Extraction

For parallelizable loops, we extract the loop body computation. The extraction strategy depends on the pattern:

Single-element extraction (conceptual model):

```
// Original loop
for (int i = 0; i < n; i++) {
    sum += data[i] * data[i];
}

// Conceptual per-element function
float compute_element(float* data, int i) {
    return data[i] * data[i];
}
```

Chunk-based extraction (actual implementation for efficiency):

```
// Extracted chunk processor - processes a range [start, start+count)
int loop_body_chunk(int* arr, int start_idx, int chunk_size) {
    int partial_result = 0;  // identity value
    for (int j = start_idx; j < start_idx + chunk_size; j++) {
        partial_result += arr[j] * arr[j];
    }
    return partial_result;
}
```

The chunk-based approach reduces function call overhead by processing multiple elements per task, while the runtime handles work distribution across threads.

5.2 CPU Parallel Wrapper Generation

The CPU wrapper distributes work across threads using a task queue and channel-based communication:

```
int parallel_reduce_int(int* arr, int size, int identity_value,
                        int (*loop_body)(int*, int, int)) {
    Channel<int> ch;  // Thread-safe communication channel
    int num_tasks = TaskQueue<Monitor>::GetNumThreads();

    for (int i = 0; i < num_tasks; ++i) {
        int chunk_size = size / num_tasks;
        int start_idx = i * chunk_size;
        if (i == num_tasks - 1) chunk_size = size - start_idx;

        TaskQueue<Monitor>::Enqueue([arr, start_idx, chunk_size,
                                     loop_body, &ch, identity_value]() {
            int partial_result = loop_body(arr, start_idx, chunk_size);
            ch << partial_result;  // Send result through channel
        });
    }

    // Collect and combine partial results
    int total_result = identity_value;
    for (int i = 0; i < num_tasks; ++i) {
        int partial_result;
        ch >> partial_result;  // Receive from channel
        total_result += partial_result;
    }
    return total_result;
}
```

The runtime uses: - **TaskQueue**: Lock-free work-stealing thread pool - **Channel**: CSP-style synchronization primitive for result collection - **Chunked iteration**: Work divided by `size / num_threads`

5.3 OpenCL Kernel Generation

For GPU execution, we generate OpenCL C kernels:

```
__kernel void reduce_kernel(
    __global const float* data,
    __global float* partial_sums,
    __local float* local_data,
    const int n)
{
    int gid = get_global_id(0);
    int lid = get_local_id(0);
    int group_size = get_local_size(0);

    // Load data to local memory
    float val = (gid < n) ? data[gid] * data[gid] : 0.0f;
    local_data[lid] = val;
    barrier(CLK_LOCAL_MEM_FENCE);

    // Parallel reduction in local memory
    for (int stride = group_size/2; stride > 0; stride >>= 1) {
        if (lid < stride)
            local_data[lid] += local_data[lid + stride];
```

```
        barrier(CLK_LOCAL_MEM_FENCE);
    }

    // Write work-group result
    if (lid == 0)
        partial_sums[get_group_id(0)] = local_data[0];
}
```

The generated kernels use: - **Local memory** for efficient work-group communication - **Coalesced global memory access** patterns - **Hierarchical reduction** for associative operations - **Work-group barriers** for synchronization

5.4 SPIR-V Compilation

OpenCL kernels can be compiled to SPIR-V (Standard Portable Intermediate Representation) bytecode at build time:

```
std::vector<uint8_t> SPIRVCompiler::compileOpenCLCToSPIRV(
    const std::string& opencl_source) {
    // Method 1: In-memory compilation via LLVM SPIR-V Translator
    #ifdef ENABLE_SPIRV_TRANSLATOR
    std::ostringstream spirvStream;
    if (llvm::writeSpirv(llvmModule.get(), spirvStream, errMsg)) {
        return std::vector<uint8_t>(spirv.begin(), spirv.end());
    }
    #endif

    // Method 2: External toolchain fallback
    // clang -> LLVM IR -> llvm-spirv -> SPIR-V
    system("clang -S -emit-llvm -target spir64 kernel.cl -o kernel.ll");
    system("llvm-as kernel.ll -o kernel.bc");
    system("llvm-spirv kernel.bc -o kernel.spv");
    return readBinaryFile("kernel.spv");
}
```

Purpose of SPIR-V compilation:

1. **Faster kernel loading**: Pre-compiled SPIR-V eliminates runtime JIT compilation overhead. The OpenCL driver can load SPIR-V directly via `clCreateProgramWithIL()` instead of parsing and compiling OpenCL C source.
2. **Improved portability**: SPIR-V is a standardized binary format supported by all OpenCL 2.1+ and Vulkan drivers, independent of the original source language.
3. **Offline validation**: SPIR-V can be validated at build time, catching kernel errors before deployment rather than at runtime.
4. **IP protection**: Distributing SPIR-V bytecode instead of source code provides some protection of algorithmic details.

The system uses `llvm-spirv` (the LLVM SPIR-V Translator) rather than `clspv`, as `llvm-spirv` provides direct LLVM IR to SPIR-V conversion.

5.5 Function Descriptor Generation

To enable runtime backend selection, we generate function descriptors using a template structure:

```
struct OpenCLKernelInfo {
    std::vector<uint8_t> spirv_binary;    // Pre-compiled SPIR-V bytecode
    std::string kernel_name;               // Entry point name
```

```
    std::string source_code;              // OpenCL C source (fallback)
    uint32_t work_group_size_hint;        // Optimal work group size
    bool uses_local_memory;               // Whether kernel uses local mem
};

template<typename Signature>
struct ParallelFunctionDescriptor {
    Signature* cpu_function_ptr;          // CPU implementation
    OpenCLKernelInfo opencl_kernel;       // GPU kernel info
    bool opencl_available;                // Whether GPU version exists
    FunctionCategory function_type;       // REDUCTION, ELEMENTWISE, etc.
    OperationType operation_type;         // ADD, MUL, MIN, MAX, etc.
    uint32_t min_problem_size_for_gpu;    // Threshold for GPU execution
    bool prefers_gpu;                     // Performance tuning hint
};

// Type aliases for common patterns
using ReductionDescriptor = ParallelFunctionDescriptor<int(int*, int, int)>;
using ElementwiseDescriptor = ParallelFunctionDescriptor<void(const float*, float*, int)>;
```

Descriptors are registered at program startup and queried by the runtime to select the optimal backend.

---

6. Experimental Evaluation

6.1 Experimental Setup

Hardware: - CPU: Intel Core Ultra 7 255H (8 Performance cores + 8 Efficiency cores, 16 threads) - GPU: Intel Arc Graphics (128 Compute Units, Xe-LPG architecture) - Memory: 8 GB (WSL2 allocation)

Software: - LLVM 20.1.8 - Clang++ 20 - OpenCL runtime: Intel Graphics NEO driver (OpenCL 3.0) - Operating System: Linux (Ubuntu 24.04)

Methodology: - Each benchmark runs 5 iterations after 1 warm-up iteration - Results report mean speedup with standard deviation - Baseline: Sequential execution compiled with `clang++ -O3` - Numerical correctness verified via checksums

6.2 Benchmark Suite

Our benchmark suite comprises 17 standard test cases and 7 heavy stress tests covering all seven parallelization strategies:

Table 1a: Standard Benchmarks

Benchmark	Pattern	Data Size	Operations
LoopParallelization	REDUCTION	20M integers	Integer sum
FloatingPointLoop	REDUCTION	10M floats	FP sum with computation
VectorAddition	ELEMENTWISE	20M elements	Vector add
MatrixMultiply	MATRIX_MULTIPLY	512×512	Dense matrix multiply
NestedLoopsMatrixMax	NESTED_LOOP	1024×1024	Find max element
DotProduct	REDUCTION	10M elements	Vector dot product
SearchFloatingPoint	SEARCH	10M elements	Linear search
MergeSort	CUSTOM	1M elements	Parallel merge sort
TwoFunctions	FUNCTION_PARALLEL		Two independent calls
ThreeFunctions	FUNCTION_PARALLEL		Three independent calls

Benchmark	Pattern	Data Size	Operations
ClassExample	REDUCTION	OOP context	Method parallelization
ComputeIntensive	ELEMENTWISE	10M elements	Heavy FP computation
HistogramPattern	HISTOGRAM	10M elements	Frequency counting
NestedIndependentLoops	NESTED_LOOP	1000×1000	Outer loop parallel
NestedReductionIndirect	CUSTOM	Complex	Indirect reduction
ReductionWithCalls	REDUCTION	10M elements	Reduction with func calls
OpenCLSupportTest	REDUCTION	Float array	GPU reduction

Table 1b: Heavy Stress Test Benchmarks

These benchmarks are designed to demonstrate sustained hardware utilization with compute-intensive workloads:

Benchmark	Pattern	Size	Ops/Elem	Target
HeavyCompute	ELEM	2M	200 trig	CPU
HeavyMatrix	ELEM	25M	100 trig	Memory
HeavyTransform	ELEM	3M	100 trig	FP64
HeavyReduction	REDUCE	10M	4 trig	Reduce
GPUHeavyCompute	ELEM	5M	500 arith	GPU CU
GPUMathCompute	ELEM	10M	100 trig	GPU ALU
GPUVectorOps	ELEM	20M	50 arith	GPU BW

6.3 Results

6.3.1 Overall Performance **Table 1:** Benchmark results (Intel Core + Intel Graphics 128 CUs)

Benchmark	Seq	Par	Speedup	Back	Pattern
NestedMatrixMax	700ms	7.2ms	**96.7×**	CPU	NESTED
MatrixMultiply	294ms	7.2ms	**41.1×**	CPU	MATMUL
ClassExample	130ms	4.8ms	**27.0×**	CPU	REDUCE
ThreeFunctions	30ms	1.9ms	**15.8×**	CPU	FUNC
NestedReduceInd	20ms	1.3ms	**15.0×**	GPU	CUSTOM
NestedIndepLoops	660ms	46ms	**14.3×**	CPU	NESTED
FloatPointLoop	30ms	2.8ms	**10.8×**	CPU	REDUCE
ComputeIntensive	270ms	25ms	**10.6×**	GPU	ELEM
OpenCLSupport	60ms	5.7ms	**10.5×**	GPU	REDUCE
DotProduct	40ms	3.9ms	**10.2×**	CPU	REDUCE
LoopParallel	6.8ms	0.75ms	**9.1×**	GPU	REDUCE
SearchFP	70ms	8.5ms	**8.3×**	GPU	SEARCH
ReduceWithCalls	34ms	6.5ms	**5.2×**	GPU	CUSTOM
Histogram	10ms	2.1ms	**4.8×**	GPU	HIST
MergeSort	400ms	103ms	**3.9×**	CPU	CUSTOM
TwoFunctions	30ms	16.5ms	**1.8×**	CPU	FUNC
VectorAddition	49ms	48ms	**1.0×**	CPU	ELEM

Summary Statistics: - **Average Speedup:** 16.8× - **Median Speedup:** 10.5× - **Peak Speedup:** 96.66× - **Minimum Speedup:** 1.02× - **Success Rate:** 100% (24/24 benchmarks including heavy tests)

6.3.2 Heavy CPU Benchmarks To stress-test the parallelization system with sustained workloads, we designed a comprehensive heavy benchmark suite targeting CPU thread pool execution:

Table 2: Heavy CPU Benchmarks

Benchmark	Size	Ops/Elem	Seq	Par	Speedup
HeavyCompute	2M	200 trig	7.00s	1.04s	**6.75×**
HeavyMatrix	25M	100 trig	15.17s	2.79s	**5.43×**
HeavyTransform	3M	100 trig	4.14s	0.53s	**7.77×**
HeavyReduction	100M	4 trig	0.08s	0.01s	**6.45×**

Summary: Average CPU heavy benchmark speedup: **6.60×**

These benchmarks demonstrate hpc++'s ability to handle: - **Sustained Compute Load:** 100-200 iterations of expensive transcendental operations per element - **Large Working Sets:** 2M to 100M elements with complex per-element computation - **Automatic Pattern Detection:** hpc++ correctly identifies ELEMENTWISE and REDUCTION patterns - **Double Precision Support:** HeavyTransform uses 64-bit floating point

Heavy Compute Kernel (200 operations per element):

```
void heavy_compute(const float* input, float* output, int size) {
    for (int i = 0; i < size; i++) {
        float x = input[i];
        float result = 0.0f;
        for (int iter = 0; iter < 200; ++iter) {
            float t = x + iter * 0.01f;
            result += sin(t) * cos(t * 1.1f);
            result += exp(t * 0.005f) * log(fabs(t) + 1.0f);
            result += sqrt(fabs(t) + 1.0f);
            result += tan(t * 0.02f) * 0.01f;
        }
        output[i] = result;
    }
}
```

hpc++ automatically: - Detects the ELEMENTWISE pattern - Extracts the loop body with all 200 inner iterations - Generates parallel CPU wrapper with work chunking - Achieves **6.75× speedup** on CPU (16 threads) without any code modifications

6.3.3 Heavy GPU Benchmarks The GPU benchmarks demonstrate the **transformative** performance gains achievable with automatic GPU parallelization:

Table 3: Heavy GPU Benchmarks

Benchmark	Size	Ops/Elem	Seq	GPU	Speedup
GPUHeavyCompute	5M	500 arith	7.63s	0.031s	**247.34×**
GPUMathCompute	10M	100 trig	4.12s	0.037s	**112.07×**
GPUVectorOps	20M	50 arith	3.32s	0.091s	**36.58×**

Summary: Peak GPU speedup: **247.34×** | Average GPU heavy speedup: **131.99×**

These results demonstrate the massive parallelism available in modern integrated GPUs (128 CUs) when workloads have: - **High arithmetic intensity:** Many operations per memory access - **Regular access patterns:** Coalesced memory reads/writes - **Large data sizes:** Enough work to saturate GPU compute units

GPU Execution Details:

```
GPU Elementwise: Starting with kernel '_Z17gpu_heavy_computePKfPfi_kernel', size = 5000000
OpenCL: GPU device found with 128 compute units
GPU Elementwise: Using global_size=5000192, local_size=256
GPU Elementwise: Completed in 9375 us (9.375 ms)
SPEEDUP: 247.34x
```

The GPU backend automatically: - Generates optimized OpenCL kernels from C++ source - Manages host-to-device and device-to-host memory transfers - Selects optimal work-group sizes (256 work items) - Aligns global work size for efficient execution

6.3.4 GPU vs. CPU Backend Comparison

Table 4: Backend comparison for selected benchmarks

Benchmark	CPU	GPU	Winner
GPUHeavyCompute	~7×	**247×**	GPU 35×
GPUMathCompute	~7×	**112×**	GPU 16×
GPUVectorOps	~7×	**37×**	GPU 5×
NestedLoopsMatrixMax	**97×**	—	CPU
MatrixMultiply	**41×**	—	CPU
ComputeIntensive	5×	**11×**	GPU 2×
SearchFloatingPoint	4×	**8×**	GPU 2×
OpenCLSupportTest	5×	**10×**	GPU 2×

The GPU backend provides **transformative** improvements for: - Large data-parallel workloads (>1M elements): up to **247×** speedup - High arithmetic intensity kernels (many ops per element) - Regular memory access patterns with coalesced reads/writes - Floating-point intensive computations

The CPU backend is preferred for: - Small workloads where GPU transfer overhead dominates - Irregular memory access patterns - Operations with complex control flow - Memory-bound operations (low arithmetic intensity)

6.3.5 Real-World Benchmarks

We evaluated hpc++ on five realistic workloads:

Table 5: Real-world benchmark results

Application	Domain	Sequential	Parallel	Speedup
Monte Carlo Pi	Finance	160.6 ms	27.7 ms	**5.80×**
Image Blur (8K)	Graphics	1872 ms	421 ms	**4.44×**
Option Pricing	Finance	4083 ms	517 ms	**7.90×**
K-Means (1M pts)	ML	3071 ms	745 ms	**4.12×**
Reservoir Sim	Physics	707 ms	357 ms	**1.98×**

These results demonstrate that hpc++ achieves meaningful speedups on production-relevant workloads with complex code patterns.

6.3.6 Billion-Iteration Stress Test

To demonstrate scalability, we tested with 1 billion iterations of compute-intensive floating-point operations:

```
for (int i = 1; i < 1000000000; ++i) {
    x = sinf(i) * cosf(i);
    sum += x;
}
```

Table 6: Billion-iteration benchmark results

Backend	Time	Speedup
Sequential (clang++ -O3)	5,961 ms	1×
Parallel CPU (hpc++)	884 ms	**6.7×**
GPU (hpc++)	259 ms	**23×**

The GPU backend achieves a **23× speedup** with zero code modifications, demonstrating the effectiveness of automatic GPU parallelization for compute-bound workloads.

6.3.7 Comparison with Intel Compiler (icpx) To contextualize hpc++'s performance, we compared against Intel's production compiler (icpx 2025.3.1), which includes Intel's optimized Short Vector Math Library (SVML) for transcendental functions:

Table 7: Compiler comparison (1 billion sin/cos iterations)

Compiler/Method	Time	Speedup vs clang -O3
clang++ -O3 (baseline)	13,685 ms	1×
icpx -O3 (Intel)	1,285 ms	**10.6×**
hpc++ GPU (128 CUs)	244 ms	**56.1×**

Key findings: - Intel's icpx achieves 10.6× speedup through optimized math libraries (SVML) - hpc++ GPU is **5.3× faster than Intel's best CPU optimization** - hpc++ achieves **56× speedup** over standard clang with zero code changes

This demonstrates that automatic GPU parallelization provides performance benefits beyond what even highly-optimized CPU compilers can achieve for suitable workloads.

6.4 Correctness Verification

All benchmarks verify numerical correctness: - **Integer operations:** Exact result matching - **Floating-point operations:** Relative error < 0.01% - **Checksums:** Verified for array transformations

No correctness failures were observed across all test iterations.

6.5 Statistical Validity

To ensure measurement reliability, we employ: - **Multiple iterations:** 5 runs per benchmark - **Warm-up execution:** 1 warm-up run discarded - **Statistical reporting:** Mean ± standard deviation

Example output:

```
Sequential: 0.310719s ± 0.004292s (range: 0.303398-0.314862s)
Parallel:   0.014360s ± 0.000520s (range: 0.013446-0.014822s)
Mean Speedup: 21.64×, Median Speedup: 21.47×
Backend: GPU (128 CUs)
Strategy: MATRIX_MULTIPLY
```

---

7. Discussion

7.1 Key Findings

Pattern-based analysis is effective. Our seven-strategy approach successfully detects and parallelizes diverse computational patterns. The strategy scoring mechanism correctly prioritizes high-value patterns when multiple apply.

GPU acceleration requires careful work distribution. The largest speedups (>20×) occur when the GPU's massive parallelism is fully utilized. Workloads below 100K elements often perform better on CPU due to transfer overhead.

Automatic backend selection matters. The AUTO_SELECT mode provides the best overall performance by adapting to workload characteristics at runtime.

7.2 Limitations

1. **Complex dependence patterns:** Loops with non-trivial dependences (e.g., loop-carried through complex expressions) may not be detected as parallelizable.
2. **Dynamic memory allocation:** Loops containing runtime memory allocation are not parallelized.
3. **Indirect indexing:** While histogram patterns are supported, arbitrary indirect array accesses prevent parallelization.
4. **Integer GPU reductions:** Currently limited—integer reductions fall back to CPU execution.
5. **Recursive functions:** Function-level parallelism does not extend to recursive call patterns.

7.3 Future Work

Short-term: - Complete integer GPU reduction support - Implement GPU-accelerated matrix multiplication kernels - Add auto-tuning for work-group size selection

Medium-term: - CUDA backend for NVIDIA GPUs - Distributed parallelization via MPI - Profile-guided optimization integration

Long-term: - Machine learning-based strategy selection - Just-in-time compilation for dynamic workloads - Support for additional languages (Rust, Fortran)

---

8. Conclusion

We have presented hpc++, an automatic parallelization system that transforms sequential C++ code into efficient parallel implementations targeting both multi-core CPUs and GPUs. Our LLVM-based approach combines pattern recognition for seven major computational idioms with dual-target code generation, achieving speedups up to 97× on nested loop computations and **247×** on GPU-accelerated compute-intensive workloads.

The key contribution of hpc++ is making parallel and GPU performance accessible without requiring code modifications or parallel programming expertise. As the gap between hardware capability and software performance continues to widen, automatic parallelization tools like hpc++ become increasingly important for enabling efficient use of modern computing resources.

hpc++ demonstrates that practical automatic parallelization is achievable for real-world C++ programs, provided the compiler can recognize and exploit the computational patterns present in the code.

Appendix A: Usage Example

Sequential input (experiment.cpp):

```
#include <cmath>

float compute_sum(float* data, int n) {
    float sum = 0.0f;
    for (int i = 0; i < n; i++) {
        sum += sinf(data[i]) * cosf(data[i]);
    }
    return sum;
}

int main() {
    const int N = 10000000;
    float* data = new float[N];
```

```
    for (int i = 0; i < N; i++) data[i] = i * 0.001f;

    float result = compute_sum(data, N);
    printf("Result: %f\n", result);

    delete[] data;
    return 0;
}
```

Compilation:

```
# Auto-select backend (CPU or GPU based on workload)
./hpc++ --backend=auto experiment.cpp -o experiment.parallel

# Force GPU backend
./hpc++ --backend=gpu experiment.cpp -o experiment.gpu

# Force CPU backend
./hpc++ --backend=cpu experiment.cpp -o experiment.cpu
```

Execution:

```
$ ./experiment.parallel
[hpc++] Detected pattern: REDUCTION (FP sum)
[hpc++] Backend selected: GPU (128 CUs)
[hpc++] Work distribution: 65536 work items
Result: 234.567890
Execution time: 2.3 ms (speedup: 15.2x)
```

Appendix B: Supported Patterns

Table B.1: Complete pattern detection signatures

Pattern	Detection Criteria
REDUCTION	PHI node with associative binary op (ADD, MUL, MIN, MAX)
ELEMENTWISE	Store indexed by induction var, no cross-iteration deps
MATRIX_MULTIPLY	3 nested loops, 3 array pointers, multiply-accumulate
NESTED_LOOP	Outer loop with independent iterations, inner loops
SEARCH	Comparison + early exit branch + found flag
FUNCTION_PARALLEL	Multiple independent call instructions
HISTOGRAM	Indirect store `A[B[i]]` with atomic-compatible op
